20	• Social interactions result in an S-shaped pattern of forecast-adoption diffusion
21 22 23	• The structure of a social network is of limited importance when agents' learning rates are high

#### 24 Abstract

Drought forecasts, particularly at seasonal scales, offer great potential for managing 25 climate risk in water resources and agricultural systems. In this context, the importance of 26 assessing the economic value of such forecasts and determining whether a decision-maker should 27 adopt them cannot be overstated. Value-assessment studies often, however, ignore the dynamic 28 29 aspects of forecast adoption, despite evidence from field-based studies suggesting that farmers' forecast-adoption behavior fits the general framework of innovation diffusion, i.e. that forecast 30 adoption is a dynamic learning process that takes place over time. In this study, we develop an 31 agent-based model of drought forecast adoption to study the role played by heterogeneous 32 economic and behavioral factors (i.e. risk aversion, wealth, learning rates), forecast 33 characteristics (i.e. accuracy), and the social network structure (i.e. inter- and intra-county ties, 34 35 change agents, self-reliance) in the process of forecast adoption and diffusion. We consider two learning mechanisms: learning by doing, represented by a reinforcement-learning mechanism, 36 and learning from others, represented by a DeGroot-style opinion-aggregation model. Results 37 show that, when social interactions between agents occur, forecast adoption follows a typical S-38 shaped diffusion curve. By contrast, when agents rely only on their own experience, the adoption 39 pattern is close to linear. Our numerical experiment shows additionally that forecasts are never 40 adopted if forecast accuracy drops below 65 percent. Finally, the proposed model also provides a 41 flexible tool with which to test the effectiveness of extension targeting strategies in facilitating 42 the diffusion of forecasts. 43

#### 44 **1 Introduction**

45 Weather and climate forecasts, particularly at seasonal scales, can potentially play an important role in mitigating the negative impacts of climate variability in agriculture and water 46 resources systems (Block, 2011; Hallstrom, 2004; Hansen, 2005). To realize this potential, 47 forecasts should be used effectively and routinely by their recipients, which likely requires 48 experimentation, practice, and reflection on experience regardless of how advanced or accurate 49 the forecasts are (Hu et al., 2006; Whateley et al., 2015). This dynamic learning aspect of 50 51 forecast adoption is often ignored in the literature, though, despite ample evidence from fieldbased studies suggesting that forecast-adoption behavior fits the general framework of diffusion 52 of innovation (Luseno et al., 2003; Rubas et al., 2008; Tarnoczi & Berkes, 2010). That is, 53 adoption of forecasts, like the adoption of any other *technology* or *innovation*, is a dynamic 54 process that takes place over time and spreads across the social system (Rogers, 2003; Rubas et 55 al., 2006; Ziervogel, 2004). 56

The central question that we address is: How do farmers (or water managers) make 57 decisions about the use of forecast information, particularly when a forecast product is relatively 58 59 unknown to them? Our approach deviates from the common modeling approach employed by forecast-valuation studies that assume that forecast users possess *perfect knowledge* of the 60 characteristics of forecasts and can process forecast information in a statistically sophisticated 61 manner (Millner, 2009). The perfect-knowledge assumption implies that forecast adoption is 62 essentially a static individual decision-making problem that can be solved simply by computing 63 the ex-ante value of forecasts (Millner, 2009; Rubas et al., 2008). Instead, we borrow from the 64 65 literature on technology adoption and the diffusion of innovation theory (Rogers, 2003) and use a bottom-up approach to model farmers' forecast-adoption choices explicitly in an agent-based 66 modeling (ABM) framework. By modeling and simulating individual farmers' heterogeneous 67

behavior as well as their interactions, ABM can capture macro-level emergent phenomena
(Bonabeau, 2002), a capability that is particularly relevant in diffusion-of-innovation studies
(Berger, 2001; Ng et al., 2011).

The decision-making context in our study is a stylized crop-allocation decision problem in which each farmer considers uncertainity about weather conditions during the crop season and chooses how to allocate land between two crops whose yields respond differently to drought conditions. We assume that farmers are rational decision-makers, but they cannot keep track of the history of their actions and experimental outcomes as well as those of their neighbors; they are in this sense *statistically unsophisticated* (Duffy, 2006; Millner, 2009). We also assume that farmers are not initially familiar with forecasts, but that they can learn about forecasts over time.

78 Learning has been recognized as a key driver in adopting a new technology. Using insights from field-based studies suggesting the importance of both individual experimentation 79 (e.g. Hu et al., 2006; Ziervogel, 2004) and social influences (e.g. Crane et al., 2010; Hu et al., 80 2006; Ziervogel & Downing, 2004) in forecast-use decisions, we consider two learning 81 mechanisms in the model: 1) learning by doing, in which users learn about an innovation largely 82 through individual experimentation and observation (Arrow, 1962; Feder et al., 1985; Lindner et 83 al., 1979); 2) learning from others, or social learning, in which users observe their neighbors' 84 experiences and retain relevant information (Besley & Case, 1993; Foster & Rosenzweig, 1995; 85 Manski, 1993; Munshi, 2004). To model how farmers learn from their own experience (i.e. 86 learning by doing), we use a behavioral model motivated by the psychological theory of 87 reinforcement learning. The cornerstone of reinforcement learning is the law of effect principle 88 developed by Thorndike (Thorndike, 1911, 1932), which suggests that the tendency to repeat an 89 action or a behavior that has succeeded will be reinforced whereas an action that has led to an 90 unfavorable outcome will be incorporated less frequently (Roth & Erev, 1995; Tesfatsion, 2006). 91

92 In reinforcement learning, choice behavior is treated as a Markov stochastic process in which the tendency associated with each possible action (in this case, adoption or non-adoption 93 94 of forecasts) is updated at every time step based on the consequences of a farmer's action in the previous time step (Brenner, 2006; Duffy, 2006). Furthermore, we assume that a farmer's 95 adoption behavior is also influenced by the behavior of other farmers in his or her social 96 neighborhood (i.e. a neighborhood defined by social interaction as opposed to geographic 97 proximity). This form of social learning is also known as a neighborhood effect (Baerenklau, 98 2015; Manski, 1993). To express how farmers are influenced by their neighbors, we use a simple 99 rule-of-thumb model based on the opinion-formation model of DeGroot (DeGroot, 1974; 100 Jadbabaie et al., 2012). 101

This study makes several contributions to the literature. We develop a behavioral-102 learning model to represent farmers' forecast-adoption behavior by considering individual 103 experimentation and the neighborhood effect. Because forecast performance, reflecting the 104 probabilistic nature of forecasts, is more uncertain than other innovations (Agrawala & Broad, 105 2002), learning could play an even bigger role in the context of forecast adoption. The 106 importance of learning has been documented by several field-based studies. For instance, a role-107 play exercise with smallholder farmers in Lesotho found that, as farmers became more familiar 108 with the forecasts provided, "using a forecast no longer seemed foreign" and they were more 109 willing to use them at the end of the experiment (Ziervogel, 2004). Millner (2009) used a 110 behavioral-learning model based on reinforcement learning in the context of the cost-loss 111 problem and showed that accounting for learning dynamics could significantly reduce the value 112

that the user obtains from forecasts. Our study extends and complements Millner's model by incorporating a social-learning mechanim, thereby accounting for the impact of social networks in forecast adoption and diffusion.

Our study also develops a flexible tool that makes it possible to better understand the 116 temporal and spatial dynamics of forecast-use diffusion, which in turn can inform the design of 117 economically efficient and effective strategies that facilitate forecast adoption. In the past two 118 decades, there has been great interest in social learning as a key determinant of the diffusion 119 process, especially in the context of agricultural technologies (Banerjee, 1992; Ellison & 120 Fudenberg, 1993). Studies have found that social networks can play a major role in diffusion of 121 innovation through both diffusion of knowledge (information) as well as diffusion of decisions 122 (Cai et al., 2015; Holloway & Lapar, 2007; Sampson & Perry, 2019). Studies have found that 123 stakeholder networks play a key role in the communication and dissemination of forecast 124 information to farmers (Nidumolu et al., 2018; Ziervogel & Downing, 2004). Yet some critical 125 elements in the diffusion process have not been carefully or rigorously studied in the context of 126 forecast adoption: How do social interactions influence forecast-adoption behavior? To what 127 extent is the structure of the social network important in diffusion of forecasts? What is the 128 cumulative effect of social structure and individuals' characteristics in the forecast-use diffusion 129 process? We identify these questions as gaps in the literature and address them in this study. 130

By explicitly modeling individual farmers' behavior as well as their learning from past 131 forecast usage and from the experiences of others, the ABM we present derives the forecast-132 133 adoption path as an emergent property of collective behaviors. Therefore, our study fundamentally differs from top-down studies (e.g. Rubas et al., 2008) that impose adoption 134 dynamics exogenously using widely accepted S-shaped adoption paths (Feder et al., 1985; 135 Rogers, 2003). As such, our modeling paradigm is similar to that used in Ziervogel et al. (2005) 136 and Bharwani et al. (2005), who investigated the impact of seasonal climate-forecast applications 137 among smallholder farmers in Lesotho and South Africa, respectively, using agent-based social-138 139 simulation models. We depart from this approach, using reinforcement learning to model how farmers' tendency to adopt a forecast evolves over time as they experiment with forecasts, which 140 also makes it possible to explore the impact of heterogeneous behavioral factors such as learning 141 142 rates on the adoption and diffusion process.

The remainder of the article is organized as follows. In Section 2, we introduce the 143 components of the agent-based model, including the crop-allocation decision problem and the 144 learning process. We also explain the model dynamics. In Section 3, we design a numerical 145 experiment that we use to demonstrate the adoption and diffusion of drought forecasts and 146 present the critical assumptions of the model. We present the results in Section 4. First, we focus 147 on the reinforcement-learning mechanism and investigate how risk aversion, wealth, and the 148 learning rate influence an agent's tendency to adopt a forecast over time. Second, we use the 149 agent-based model to investigate the temporal and spatial dynamics of forecast adoption and 150 diffusion in a hypothetical agriculture-dominated case-study area. In Section 5, we use the model 151 to demonstrate the effects of strategic targeting, asymmetrical learning, and forecast accuracy on 152 the diffusion process. Finally, in Section 6, we conclude with a summary of the findings, the 153 study limitations, and future work. 154

#### 155 **2 Model**

In this section, we introduce a behavioral model of forecast adoption and diffusion in 156 which decision-makers (DMs) learn about the usefulness of drought forecasts over time. DMs 157 also decide whether to use forecasts when making planting choices, to which we refer as 158 adopting the forecast. We focus our study on how the probability of forecast adoption evolves 159 over time. Learning is stochastic and based on an agent's own experience (i.e. learning by doing) 160 and on the experiences of *neighbors* in the agent's social network (i.e. social learning). To 161 represent learning by doing, we use a behavioral model known as reinforcement learning (Bush 162 & Mosteller, 1951, 1953; Roth & Erev, 1995). To account for learning from others, we use a 163 DeGroot-style learning model of belief aggregation (DeGroot, 1974; Golub & Jackson, 2010; 164 Jadbabaie et al., 2012). We now describe the decision-making problem, including these learning 165 components, in greater detail (refer to Appendix C for a list of notations used in this study). 166 Figure 1 presents a conceptual framework of the proposed model. 167

168

Figure 1. Conceptual framework of the model. (a) shows a simple representative social network
structure (or topology) and (b) shows various components of the model for agent a<sub>3</sub>, as an
example. Note that, in this network, agents a<sub>2</sub> and a<sub>4</sub> are neighbors of agent a<sub>3</sub> while agent a<sub>1</sub> is

not.

172

#### 173 2.1 Decision-making Context: Hedging against Drought

Consider a crop-allocation problem involving two crops, A and B, where a DM must 174 determine what proportion of his or her land to allocate to each crop given the uncertainty 175 associated with future weather. Without loss of generality, suppose that the weather event is a 176 drought. Let  $\theta \in \Theta = \{0,1\}$  be the random variable representing the state of the weather, where 177  $\theta = 0$  and  $\theta = 1$  correspond to no-drought (or normal) and drought conditions, respectively. 178 Denote  $p(\theta)$  as the DM's subjective belief regarding the probability that state  $\theta$  occurs. As such, 179  $p(\theta)$  embodies DM's knowledge about the uncertain event (Lawrence, 1999), which could be 180 based on the event's historical probability (also called *climatological information*) and the DM's 181 182 experience (Johnson & Holt, 1997; Sherrick et al., 2000). Suppose that the crop yield (per unit area of land) for crops A and B is a function of the weather alone, denoted by  $y^{A}(\theta)$  and  $y^{B}(\theta)$ , 183

respectively. We assume that crop *A* is more drought-tolerant and has lower yield variability, while crop *B* is a high-yield variety whose yield falls off significantly in drought conditions, i.e.  $y^{B}(1) < y^{A}(1) < y^{B}(0)$ .

187 Let  $x \in [0,1]$  be the fraction of land that the DM allocates to crop *A* prior to the 188 realization of  $\theta$  (hence, 1 - x is the land fraction allocated to *B*). The DM's payoff function can 189 be written as:

190 
$$\pi(x,\theta) = \omega + x \cdot y^{A}(\theta) + (1-x) \cdot y^{B}(\theta) - c(\theta), \qquad (1)$$

where  $\pi(x,\theta) = \pi$  is the normalized payoff given state  $\theta$  and decision x,  $\omega$  is the DM's 191 normalized initial wealth, and  $c(\theta)$  is the normalized total non-land cost of crop production (e.g. 192 fertilizer and labor costs). We normalize  $\omega$  and  $c(\theta)$  by land area and crop price, respectively, 193 and assume that the prices of the two crops are equal and do not depend on the occurrence of 194 drought. Thus,  $\pi$ ,  $\omega$ , and c are all expressed in the same units as y (yield per unit area), which 195 we denote by u. We assume that the DM is a utility maximizer whose risk preferences are 196 197 characterized by an increasing von Neumann-Morgenstern utility function,  $U = U[\pi(x, \theta)]$ , as presented in Equation 2: 198

199 
$$U = U[\pi(x,\theta)] = \begin{cases} \frac{\pi^{1-r}}{1-r} & r \neq 1\\ \ln \pi & r = 1 \end{cases},$$
 (2)

where  $r \ge 0$  is the Arrow-Pratt coefficient of relative risk aversion. The above-defined utility 200 function belongs to a class of utility functions with constant relative risk aversion (CRRA) and is 201 widely used in the economics literature (Mas-Colell et al., 2012). In CRRA utility functions, 202 higher values of r correspond to more risk-averse behavior. One important feature that CRRA 203 utility functions exhibit is that the risk premium for an absolute risk (a risk that is expressed in 204 dollars as opposed to a share of the DM's wealth) is a decreasing function of wealth, i.e. 205 wealthier individuals are more willing to take absolute risks. See Gollier (2001) for more 206 information about risk characterization and utility functions; see Wakker (2008) for more details 207 208 about the CRRA utility function. Therefore, the DM's optimization problem is given in Equation 3: 209

210 
$$\max_{x} E_{\theta}[U] = \sum_{\theta=0}^{1} p(\theta) \cdot U[\omega + x \cdot y^{A}(\theta) + (1 - x) \cdot y^{B}(\theta) - c(\theta)], \quad (3)$$

where  $E_{\theta}$  is the expectation operator taken with respect to  $p(\theta)$ . Hence, the optimal allocation decision,  $x^*$ , must satisfy the following first-order condition:

213 
$$\sum_{\theta=0}^{1} p(\theta) \cdot \left( \frac{y^{A(\theta)} - y^{B}(\theta)}{\left( \omega + x^* \cdot y^{A(\theta)} + (1 - x^*) \cdot y^{B(\theta)} - c(\theta) \right)^r} \right) = 0.$$
(4)

Because  $\Theta = \{0,1\}$ ,  $p(\theta)$  can be characterized by a single parameter  $p_1 \coloneqq p(1)$ , defined as the DM's *belief* that a drought will occur. Consequently,  $p(0) = 1 - p_1$ . See Appendix A for a sensitivity analysis demonstrating how optimal decision  $x^*$  changes with  $r, p_1$ , or  $\omega$ .

#### 217 2.2 Learning-by-Doing

According to Brenner (2006), there are two fundamentally different ways of learning: reinforcement learning and cognitive learning. In reinforcement learning, the learning mechanism does not involve any conscious reflection on a problem, and therefore people are not always aware that they are learning. By contrast, cognitive learning is based on reflections about

actions and consequences, which requires active thinking and potentially involves processing 222 statistical information (Brenner, 2006). Although people are able to reflect on their actions and 223 consequences, in most cases they lack the cognitive capacity to reflect on all their actions. As a 224 result, their reflections are likely to be distorted by cognitive biases (Brenner, 2006; Marx et al., 225 2007; Tversky & Kahneman, 1974). In reinforcement learning, on the other hand, the learning 226 mechanism is based on an association between a behavior and its consequences; in other words, 227 the behavior changes because of the resulting consequences. Reinforcement learning is 228 particularly relevant when a DM is statistically unsophisticated, i.e. when he or she does not have 229 the statistical ability to process and quantify forecast performance (Duffy, 2006; Millner, 2009). 230 In this study, we use reinforcement learning to model how individuals learn from experience. 231

The learning mechanism in reinforcement learning is based on *reward* and *punishment*: if 232 an action leads to a positive outcome, there is a higher chance that that action is chosen in the 233 next time step; similarly, actions that result in negative outcomes are more likely to be avoided. 234 One of the first mathematical models of reinforcement learning was developed by Bush and 235 Mosteller (1951, 1953). The Bush-Mosteller model is a stochastic learning model in which 236 choice behavior is described using a probabilistic distribution of alternatives rather than a binary 237 choice framework, and the probability associated with each action is updated during the learning 238 process using a simple linear rule. Cross (1973) placed the Bush-Mosteller model in an economic 239 240 context and extended it to account for rewards of differing strengths. Brenner (1999, 2006) further generalized the Bush-Mosteller model by defining reinforcement strength in such a way 241 that all rewarding (punishing) outcomes are reflected by positive (negative) reinforcement 242 strengths. Roth and Erev (1995) also developed a reinforcement-type learning algorithm to track 243 experimental data across various multi-player games that are analyzed in the experimental 244 economics literature. In the Roth-Erev model, instead of directly updating the probability of 245 choosing an action, an intermediate variable called *propensity towards an action* is employed. 246 This variable is updated once an action is performed and is used to calculate the probability 247 associated with that action. Here, we use a reinforcement-learning algorithm based on both the 248 249 Bush-Mosteller and Roth-Erev models. The algorithm used here has two important features. First, it is *memoryless*, which corresponds to real-world behavior that is motivated by spur-of-250 the-moment decisions (Rahimian & Jadbabaie, 2017). Second, it captures the spontaneous 251 recovery phenomenon (Rescorla, 2004; Thorndike, 1932), which makes it possible for nearly 252 abandoned behaviors (or actions) to quickly increase in frequency if they result in positive 253 254 outcomes (Millner, 2009).

We now formulate reinforcement learning mathematically. Suppose that DMs have 255 costless access to a probabilistic drought forecast when crop-allocation decisions are being made. 256 The forecast, denoted by  $p_d$ , indicates the probability that a drought will occur;  $p_d \in \mathcal{F}$ , where  $\mathcal{F}$ 257 is a finite set of possible forecasts. Let  $z_{i,t}$  be DM *i*'s binary forecast-adoption decision at time 258 step t, where  $z_{i,t} = 1$  indicates that the DM follows (or adopts) the forecast in making the crop-259 allocation decision. Following the Roth-Erev reinforcement-learning algorithm, we define 260  $h_{i,t} \in [0,1]$  as the DM's propensity or tendency towards adopting the forecast at time t. As there 261 are only two decision alternatives, the tendency towards not adopting the forecast (or using 262 climatological information) is  $1 - h_{i,t}$ . The reinforcement-learning framework determines how 263 the adoption tendency,  $h_{i,t}$ , evolves as a function of the DM's past decisions and outcomes. 264 Using an updating rule based on a generalized form of the Bush-Mosteller model from Brenner 265 (2006), the adoption tendency in the next time step,  $h_{i,t+1}$ , follows Equation 5: 266

267

$$h_{i,t+1} = h_{i,t} + \begin{cases} L(S_{i,t},\tau_i) \cdot (1-h_{i,t}) & if \quad S_{i,t} \ge 0\\ \\ L(S_{i,t},\tau_i) \cdot h_{i,t} & if \quad S_{i,t} < 0 \end{cases}$$
(5)

where  $L(\cdot)$  is the learning function,  $S_{i,t}$  is the *reinforcement strength* (expressed in unit u), and  $\tau_i$ is the *learning rate* (expressed in unit  $u^{-1}$ ). We follow convention and use a linear learning function:  $L(S_{i,t}, \tau_i) = S_{i,t} \cdot \tau_i$ . To ensure that  $h_{i,t+1}$  remains between 0 and 1, we restrict  $\tau_i \cdot max |S_{i,t}| \le 1$ . Given the formulation in Equation 5, if  $S_{i,t} \ge 0$  (i.e. the reinforcement strength is positive), the tendency of the DM to choose the action that would have led to the positive outcome will increase in the next time step. Thus, at each time step, the past is implicitly contained in the current value of  $h_{i,t}$  (Brenner, 2006).

The choice of reinforcement strength is critical in this learning framework (Millner, 2009). In our case, the most natural choice for  $S_{i,t}$  is the *ex post* value of the forecast, denoted by  $V^{exp}$ :

278 
$$S_{i,t} = V_{i,t}^{exp} = \pi \left( x_{i,t}^{*,f}, \varphi_{i,t} \right) - \pi \left( x_{i,t}^{*,c}, \varphi_{i,t} \right).$$
(6)

Variables  $x_{i,t}^{*,f}$  and  $x_{i,t}^{*,c}$  are optimal crop-allocation decisions when a DM does or does not use the 279 forecast information, respectively, at time t. If the forecast is not adopted, the DM makes the 280 decision based on his or her own belief about drought occurrence, i.e.  $p_{i,1}$ ;  $\varphi_{i,t} \in \Phi = \{0,1\}$  is 281 the realized state of the weather at time t, where  $\varphi = 1$  indicates that a drought event has 282 occurred. Note that  $V^{exp}$  is also expressed in the baseline unit u. The expost value of the 283 forecast denotes the value the DM would have received if he or she had made the crop-allocation 284 decision based on the forecast. Learning occurs only when  $x_{i,t}^{*,f} \neq x_{i,t}^{*,c}$  (otherwise,  $S_{i,t} = 0$  and 285  $h_{i,t+1} = h_{i,t}$ ). When  $S_{i,t} > 0$  (hence  $V_{i,t}^{exp} > 0$ ), the decision to adopt the forecast is reinforced; 286 whereas when  $S_t < 0$  the probability that the forecast is adopted in the next time step declines. 287 As such,  $S_{i,t}$  can be interpreted as a measure of *regret* or *happiness* regarding forecast adoption 288 (Millner, 2009). 289

In our formulation, the adoption choice at each time step (i.e.  $z_t$ ) is independent of 290 adoption choices in previous time steps, and agents treat adoption and discontinuance decisions 291 292 symmetrically. This diverges from the common approach in modeling technology adoption, where agents are assumed to continue using a new technology forever once they decide to adopt 293 294 it (Ellison & Fudenberg, 1993). The rationale for assuming symmetrical behavior in our model is that, unlike in most other technological transitions, here no cost would be incurred if agents 295 decide to switch between the two available options, i.e. adopting or not adopting a drought 296 forecast. 297

#### 298 2.3 Social Learning

Consider a set  $\mathcal{M} = \{1, 2, ..., m\}$  of agents interacting over a *social network*. Suppose that the underlying structure of the social network is known and can be represented by a directed graph with *m* vertices. Each vertex corresponds to an agent and a directed edge is present from vertex (agent) *j* to vertex *i* only if agent *j* is a *neighbor* of agent *i*. In that case, agent *i*'s beliefs can be influenced by agent *j*'s beliefs. For each agent  $i \in M$ , define  $\mathcal{N}_i$  as the set of agents in agent *i*'s *social space* (Akerlof, 1997), with  $|\mathcal{N}_i| = n_i$ . The social network can be summarized by matrix  $\Delta = [\alpha_{ij}]_{m \times m}$ , defined as the *matrix of social interaction* (Jadbabaie et al., 2012), where for each agent *i*,  $\alpha_{ij} \ge 0$  determines the *weight* that agent *i* assigns to the beliefs of agent *j*, and the weights must satisfy  $\sum_{j=1}^{m} \alpha_{ij} = 1$ . Note that  $\alpha_{ij} = 0$  if agent *j* is not a neighbor of agent *i* (or  $j \notin \mathcal{N}_i$ ).  $\alpha_{ii}$  is the weight that agent *i* assigns to his or her own belief, which is referred to as *self-reliance*, and  $\sum_{j \in N_i} \alpha_{ij} = 1 - \alpha_{ii}$ . Therefore, matrix  $\Delta$  determines both *social connections* and the extent of *social interactions* (Molavi et al., 2018).

The social-learning component of our model is based largely on the belief-aggregation model of *DeGroot* (1974). In DeGroot-style models, agents update their beliefs as a convex combination (i.e. weighted average) of the beliefs of their neighbors. The *weights* determine the *trust* that agents have for their neighbors (Acemoglu & Ozdaglar, 2011; DeGroot, 1974). Let  $h_{i,t}$ be agent *i*'s tendency to adopt the forecast at time step *t*, as in Section 2.2. Using the DeGroot model of social learning, agent *i* updates the likelihood that he or she will adopt the forecast (i.e.  $h_{i,t+1}$ ) as follows:

318 
$$h_{i,t+1} = \alpha_{ii} \cdot h_{i,t} + \sum_{j \in \mathcal{N}_i} \alpha_{ij} \cdot h_{j,t}.$$
 (7)

In the next section, we discuss the dynamics of the model and provide a framework within which we embed individual reinforcement-based learning into a DeGroot-style sociallearning component.

#### 322 **2.4 An Agent-based Modeling Framework**

323 We now integrate the components presented in Sections 2.1-2.3 into an agent-based model of forecast adoption and diffusion. Figure 2 shows the flowchart of the proposed model. 324 For all agents  $(i \in \mathcal{M})$ , the risk attitude (represented by the coefficient of risk aversion,  $r_i$ ), 325 adoption threshold  $(h_i^*)$ , initial wealth level  $(\omega_i)$ , learning rate  $(\tau_i)$ , belief about drought 326 occurrence  $(p_{1_{i,t}})$ , and initial adoption tendency  $(h_{i,1}^{initial})$  are taken as given. The structure of the 327 social network ( $\Delta = [\alpha_{ij}]_{m \times m}$ ) is also known. Time steps are indexed by t = 1, 2, ..., T. Each 328 time step represents a crop season. Let  $h_{i,t}^{initial}$  and  $W_{i,t}$  be agent i's adoption tendency and 329 wealth at the *beginning* of time step t, i.e. before crop-allocation decisions are made; note that 330  $W_{i,1} = \omega_i$ . At the beginning of each time step t, each agent receives a probabilistic drought 331 forecast  $(p_{d_{i,t}})$ . Agents then learn from their neighbors' forecast adoption tendencies and update 332 their own beliefs according to Equation 8: 333

334 
$$\forall i: h_{i,t} = \alpha_{ii} \cdot h_{i,t}^{initial} + \sum_{j \in \mathcal{N}_i} \alpha_{ij} \cdot h_{j,t}^{initial}.$$
 (8)

To convert agent *i*'s stochastic choice behavior (i.e.  $h_{i,t}$ ) into deterministic behavior (i.e.  $z_{i,t}$ ), a threshold (or cut-off value) defined as  $h_i^*$  is used, as indicated in Equation 9:

$$z_{i,t} = \begin{cases} 1 \\ 0 \end{cases}$$

$$=\begin{cases} 1 & if \quad h_{i,t} \ge h_i^* \\ 0 & if \quad h_{i,t} < h_i^* \end{cases}$$
(9)

Note that, in our formulation, we impose the cut-off value as an exogenous parameter. 338 339 Alternatively, the cut-off value could be derived endogenously by comparing the expected utilities of forecast adoption and non-adoption (i.e.  $z_{t} = 1$ 340 if  $E\left[U[\pi(x_{i,t}^{*,f},\theta)]\right] > E\left[U[\pi(x_{i,t}^{*,c},\theta)]\right]$ , e.g. as shown in Ellison and Fudenberg (1993) and 341

Confidential manuscript submitted to Water Resources Research

Adhvaryu (2014). We cannot, however, derive an explicit relationship between an agent's adoption tendency and the cut-off value because of the functional forms of the utility function and the payoff function.

Once their adoption decisions are made, agents make their crop-allocation decisions ( $x_{i,t}^*$ ) following Equation 10:

$$x_{i,t}^* = egin{cases} x_{i,t}^{*,f} & if \quad z_{i,t} = 1 \ x_{i,t}^{*,c} & if \quad z_{i,t} = 0 \end{cases}.$$

(10)

After the actual state of the weather is realized (i.e.  $\varphi_{i,t}$ ), Equation (6) is used to calculate the reinforcement strength ( $S_{i,t}$ ), and the adoption tendency at the end of time *t* will be calculated according to Equation (11):

351 
$$h_{i,t}^{final} = h_{i,t} + \begin{cases} S_{i,t} \cdot \tau_i \cdot (1 - h_{i,t}) & if \quad S_{i,t} \ge 0\\ S_{i,t} \cdot \tau_i \cdot h_{i,t} & if \quad S_{i,t} < 0 \end{cases}$$
(11)

We assume that agriculture is the main economic activity that contributes to the wealth of each agent; as such, the consequence of agricultural decision-making at each time step directly affects agents' wealth. Agent *i*'s wealth at time t+1 ( $W_{i,t+1}$ ) can be written as follows:

355 
$$W_{i,t+1} = W_{i,t} + \pi(x_{i,t}^*, \varphi_{i,t}).$$
(12)

At the end of time step *t*, the cumulative *ex post* payoff or cumulative gain  $(\pi_t^{cum})$  is calculated as follows:

358 
$$\pi_t^{cum} = \sum_{t'=1}^t \pi(x_{i,t'}^*, \varphi_{i,t'}).$$
(13)

At this point, time step t is completed and period t + 1 begins.

**Figure 2.** Flowchart of the proposed ABM simulating forecast adoption and diffusion.

#### 362 **3 Experimental Set-up and Assumptions**

We design an experiment to demonstrate how various factors related to DMs' 363 characteristics and their social network structure influence the dynamics of the forecast-diffusion 364 process. The hypothetical case-study area, as shown in Figure 3, is an agriculture-dominated 365 region consisting of 25 clusters (representing counties, communities, or villages), with 25 agents 366 (representing farmers) in each cluster. Agents may interact with other agents in their social 367 spaces (also referred to as social neighborhoods) and learn from their experiences. This 368 interaction, which stimulates social learning, takes the form of communication of adoption 369 beliefs,  $h_{i,t}$ . For all agents, the decision-making problem follows the one introduced in Section 370 2.1 with  $y^{A}(0) = 0.06$ ,  $y^{A}(1) = 0.03$ ,  $y^{B}(0) = 0.08$ ,  $y^{B}(1) = 0.01$ , c(1) = 0.04, and 371 c(0) = 0.05, all expressed in the baseline unit u. 372

We assume that the social neighborhood for each agent is dictated by his or her inter- and intra-county social ties, which are represented by two binary variables:  $SI_{in} \in \{0,1\}$  for intracounty ties, and  $SI_{out} \in \{0,1\}$  for inter-county ties. The extent of social interactions (i.e. the weights assigned to neighbors' beliefs) is represented by the matrix  $\Delta = [\alpha_{ij}]_{m \times m}$ , where  $\alpha_{ij} = 0$  if  $j \notin \mathcal{N}_i$ ;  $\sum_{j \in \mathcal{N}_i} \alpha_{ij} = 1 - \alpha_{ii}$ , and  $\alpha_{ii}$  is each agent's self-reliance. When both  $SI_{in}$  and  $SI_{out}$  are zero, there is no social interaction and agents rely only on their own experience (i.e.  $\alpha_{ii} = 1$ ). When either of  $SI_{in}$  and  $SI_{out}$  is one, it is assumed that the agents are equally influenced (i.e. equal weights) by their own and other agents' beliefs that circulate in their social neighborhoods, unless stated otherwise.

We assume that the climatological probability of a drought event in the case-study area is 382 30 percent; that all agents share the same belief about the possibility that a drought event will 383 occur, which is assumed to be equal to the climatological probability of drought in the area; and 384 that this belief remains unchanged throughout the entire simulation, i.e.  $\forall i, t: p_{1i,t} = 0.3$ . 385 Although these assumptions may not be necessarily accurate, they do not impact the purpose of 386 this study and we leave investigating them to future work. Finally, we assume that the same time 387 series of drought events is observed by all agents in the case-study area. Based on the time series 388 of drought events, an approach similar to ensemble forecasting is used to generate probabilistic 389 drought forecasts at a specified accuracy. Specifically, we assume that a probabilistic drought 390 forecast at time  $t(p_{d_t})$  is generated by a system that produces deterministic forecasts that have 391 an accuracy of  $\kappa$ . As such,  $p_{d_t}$  is defined as  $p_{d_t} = \frac{\sum_{i=1}^N I_{\{\eta_i=1\}}}{N}$ , where N is the total number of 392 ensemble members and  $\eta_i$  is the deterministic forecast produced by ensemble member *i* (see 393

Appendix B for additional details). Unless otherwise noted, we assume that  $\kappa = 0.7$ .

The key parameters of each DM are: the initial adoption tendency, the adoption threshold, the coefficient of risk aversion, initial wealth, and the learning rate. We assume that agents initially do not adopt the forecast by setting  $h_{i,1}^{initial} = 0.5$ . We set the adoption threshold at 0.65 for all agents (i.e.  $\forall i, t: h_{i,t}^* = 0.65$ ). For the other three parameters as well as for parameters related to the topology of social networks (e.g. inter- and intra-county ties), we conduct sensitivity analyses.

 adoption. (a) County locations. (b) Locations of the agents within each county. (c) Topology of
 the social network for agent #301.

#### 406 **4 Results**

405

We first illustrate how various social-psychological and economic factors (i.e. risk aversion, r, initial wealth level,  $\omega$ , and the learning rate,  $\tau$ ) influence an individual's learning and adoption behavior. We then explore how these factors influence the aggregate rate of forecast adoption and diffusion.

### 411 **4.1 Reinforcement Learning and Belief Evolution**

A DM's learning from the consequences of past adoption (or non-adoption) decisions is reflected in his or her tendency to follow the forecast (*h*), which depends on the reinforcement strength (*S*) and the learning rate ( $\tau$ ). Figure 4 shows one possible trajectory of the adoption tendency for a DM with a given risk-aversion coefficient (*r*), initial wealth ( $\omega$ ), and learning rate ( $\tau$ ). This trajectory is based on the time series of drought events and forecasts shown in Figure 4a. The Brier skill score (Wilks, 2006) for the forecasts shown in the figure is *BSS* = 0.43, which indicates that forecasts are on average more accurate than the climatological information.

When the learning rate is constant, the change in the DM's adoption tendency depends only on the current value of the reinforcement strength. This behavior reflects the key feature of the reinforcement-learning mechanism where the entire relevant history of the DM's behavior is implicitly contained in the current value of his or her adoption tendency (Brenner, 2006). No learning occurs when reinforcement strength is zero (i.e., S = 0). Figure 4b shows that, at first (t < 22), there is only one instance without learning. As a result, the DM's adoption tendency

#### Confidential manuscript submitted to Water Resources Research

changes frequently in this period, as shown in Figure 4c. Because there are more instances with S > 0, the adoption tendency exhibits an increasing trend. In the second portion (t > 22), the reinforcement strength is mostly zero; in those instances, the adoption tendency remains unchanged. The non-zero values of reinforcement strength are, however, relatively large and mostly positive, leading to the overall increasing trend in the DM's adoption tendency.

To further explain the two patterns, it is important to consider the decision-making 430 context and the parameters that influence decisions under uncertainty. At first, the DM relies on 431 climatological information (i.e.  $p_1 = 0.3$ ) because the tendency to use the forecast remains under 432 the adoption threshold (i.e.  $h_t < h^* \rightarrow x_t^* = x_t^{*,c}$ ). The combination of initially low wealth and 433 high risk aversion results in conservative crop-allocation decisions that are intended to minimize 434 435 the potential impact of drought; i.e. a large fraction of land is allocated to crop A, which is a more drought-tolerant crop with lower yield variability (see Appendix A). For instance, the DM 436 allocates 44 percent of the land to crop A at t = 1 (i.e.  $x_1^* = x_1^{*,c} = 0.44$ ). For this DM, a 437 forecast with  $p_d > p_1 = 0.3$  that is followed by a drought event will result in a positive *ex post* 438 value, thereby increasing the DM's tendency to adopt the forecast. This means that, if the DM 439 had relied on such a forecast (instead of using the climatological information), a larger fraction 440 of land would have been allocated to crop A (i.e.  $x_1^{*,f} > 0.44$ ), which would have led to higher 441 profit under drought conditions and consequently larger  $S_t = V_t^{exp}$ . A similar argument holds 442 true for a forecast of  $p_d < p_1 = 0.3$  that is followed by normal climatological conditions. On the 443 other hand, the *ex post* value associated with a forecast of  $p_d < p_1$  that is followed by a drought 444 event or a forecast of  $p_d > p_1$  that is followed by normal conditions is negative, which decreases 445 the DM's tendency to adopt the forecast. Because forecasts are on average more accurate than 446 climatological information (BSS = 0.43), instances with  $V^{exp} > 0$  occur more frequently, which 447 leads to an increasing trend in the adoption tendency. 448

449 As the DM's wealth increases over time (see Figure S1), his or her treatment of uncertainty approaches that of a risk-neutral DM (even though r = 10); as a result, for  $t \ge 28$ , 450 the optimal crop land allocation would be to plant only crop B (i.e.  $x_t^{*,c} = 0$ ) if the decision is 451 based on climatological information. As a result, the forecast triggers learning (i.e.  $V_t^{exp} > 0$ ) 452 only if it leads to a decision that includes crop A in the mix of crop allocation (i.e.  $x_t^{*,f} \neq 0$ ), 453 which happens when  $p_d$  is relatively large. Even though these learning instances are not frequent 454 455 in the remainder of the simulation (i.e.  $t \ge 28$ ), because the corresponding reinforcement strength is positive in most cases the adoption tendency usually increases when learning is 456 triggered, except when S < 0 (see Figure 4b and Figure 4c). For smaller values of  $p_d$ , decisions 457 made with and without forecasts are similar (i.e.  $x^{*,c} = x^{*,f}$ ). Therefore, those instances do not 458 contribute to learning. In the scenario shown in Figure 4, the DM's tendency to adopt the 459 forecast exceeds the threshold at t = 39 for the first time, and the DM continues following the 460 forecasts until the end of the simulation, which results in a 23 percent higher cumulative 461 economic gain than if he or she had maintained the business-as-usual practice (i.e. relying on 462 climatological information). The DM's economic gain would however have been 37 percent 463 higher than in a business-as-usual scenario had the forecasts been adopted from the beginning 464 (see Figure S1). 465

466

Figure 4. Evolution of an agent's tendency to adopt drought forecast information. (a) Shows one possible time series of drought forecasts, (b) shows the corresponding time series of *ex post* forecast values, and (c) shows the corresponding trajectory of the forecast adoption tendency. Here, r = 10,  $\omega = 0.5$ , and  $\tau = 3$ .

Figure 5 shows that the forecast-adoption tendency among DMs with higher learning 472 rates, higher wealth, and lower risk aversion follows a steeper trajectory. As Equation 5 473 indicates, the learning rate determines the extent of a DM's response to the stimulus provided by 474 the consequences of forecast adoption (or non-adoption) decisions. Higher values of the learning 475 476 rate indicate that the DM is more susceptible to being *triggered* by the consequences of his or her past decisions, thereby representing a rapid learning behavior (Figure 5a); as such, DMs whose 477 learning rates are higher begin following the forecasts earlier. Figure 5a also shows that, when 478 479 the learning rate is high (i.e.  $\tau = 5$ ), the adoption tendency drops significantly after only one *punishing* outcome (for example the drop at t = 94). This behavior, which is known in the 480 reinforcement-learning literature as *spontaneous recovery*, implies that low-probability actions 481 (in this case, not following the forecast) that have been abandoned by the DM could be quickly 482 reinforced after a positive (*rewarding*) outcome (note that a punishing outcome for adoption is a 483 484 rewarding outcome for non-adoption) (Brenner, 2006; Millner, 2009). On the other hand, when the learning rate is low (i.e.  $\tau = 1$ ), even though the tendency to adopt the forecast continues to 485 increase monotonically, it takes much longer for the DM to begin using it. 486

Figure 5b shows that the forecast-adoption tendency of a less risk-averse DM grows more rapidly. This is because, at first, crop-allocation decisions are made based on climatological information (i.e.  $p_1 = 0.3$ ) and, therefore, for a DM with low risk aversion (i.e. r = 0.5) the

fraction of land allocated to crop A is zero because crop B has a higher expected yield. Therefore, 490 the *ex post* value of forecasts is non-negative when  $x^{*,f} \neq 0$ , which corresponds to situations 491 with relatively high values of  $p_d$ . Because droughts occur 30 percent of the time on average (i.e. 492  $p_1 = 0.3$ ) and forecasts have high accuracy (i.e.  $\kappa = 0.7$ ), instances with high  $p_d$  are not 493 frequent. Because such instances are followed by a drought event in most cases, they provide 494 high value to the DM, resulting in a greater increase in the forecast-adoption tendency. On the 495 other hand, for a highly risk-averse DM (i.e. r = 10), even though learning occurs more 496 frequently at first, there are more instances where  $V^{exp} < 0$ , and the reinforcement strength is 497 lower than it is in the case of a DM with r = 0.5 (see Figure S2). As a result, such a DM's 498 tendency to adopt forecasts increases at a slower pace. As the DM's wealth increases over time, 499 however, the impact of risk aversion declines and the adoption tendency follows a very similar 500 trend to the one observed where r = 0.5. 501

Similar arguments can be used to explain how the DM's initial wealth influences his or 502 her learning pattern. The combination of r = 10 and  $\omega = 0.25$  represents an extreme case of 503 conservative decision-making to minimize the potential impact of drought, and the DM will 504 decide to plant crop A regardless of whether he or she relies on climatological information or 505 forecasts. As such, the *ex post* value of forecasts is very low at first, leading to small changes in 506 the adoption tendency. This is the opposite of what is observed where  $\omega = 1$  (see Figure 5c and 507 Figure S2). As in the previous case, as the DM's wealth increases the decisions, *ex post* values, 508 and consequently the adoption tendency for DMs with lower initial wealth become similar to that 509 of a DM with large initial wealth (i.e.,  $\omega = 1$ ). 510

511

Figure 5. Sensitivity of the forecast adoption tendency to a DM's parameters based on the time series of forecasts and drought events shown in Figure 4 with varying values of (a) learning rate  $\tau$  (with fixed  $\omega = 0.5$  and r = 10), (b) risk aversion r ( $\omega = 0.5$  and  $\tau = 3$ ), and (c) initial wealth  $\omega$  (r = 10 and  $\tau = 3$ ).

516

#### 517 4.2 Agent-based Model of Forecast Diffusion

In this section, we investigate learning and the dynamics of forecast diffusion in a social setting. Figure 6 shows the diffusion curve under three scenarios of social interaction: 1) full interaction, in which agents interact with all their neighbors, both inside and outside of their

counties (i.e.  $SI_{in} = 1, SI_{out} = 1$ ); 2) intra-county interactions only, in which agents interact 521 only with neighbors inside their counties (i.e.  $SI_{in} = 1, SI_{out} = 0$ ); and 3) no interactions, in 522 which agents learn based only on their own experience (i.e.  $SI_{in} = 0, SI_{out} = 0$ ). We assign 523 agents' learning rates ( $\tau$ ), risk aversion (r), and initial wealth ( $\omega$ ) randomly, assuming that each 524 is normally distributed with  $\tau \sim N(1.5,0.1)$ ,  $r \sim N(10,1)$ , and  $\omega \sim N(0.5,0.05)$  (see Figures S4–S6 525 for additional details). The diffusion curve for the full-interaction scenario is generally S-shaped, 526 exhibiting logistic-type growth, which is consistent with the typical adoption path suggested in 527 the diffusion-of-innovation literature (Mansfield, 1961; Rogers, 2003; Stoneman, 1983). Instead 528 529 of exhibiting a typical monotonically increasing trend, though, the results exhibit a fluctuating trend. This is because we consider *discontinuance* in our model; in other words, agents may 530 decide to discontinue using the forecast and base their decisions on climatological information 531 despite having adopted the forecast earlier. The fluctuations are more frequent at first because 532 533 the forecast-adoption tendency is, on average, closer to the adoption threshold of  $h^* = 0.65$ during this period. 534

This S-shaped pattern we observe regarding adoption can be explained as follows. At 535 first, agents exhibit a low forecast-adoption tendency, and decisions are therefore made based on 536 537 climatological information. Because forecasts are on average more accurate than climatological information, however, agents gradually learn from their own and their neighbors' experience and 538 form a greater tendency to use forecasts. This learning process varies across agents because of 539 the heterogeneity in agents' behaviors and neighborhoods. As such, some agents adopt forecasts 540 earlier than others. These agents are called *early adopters*. Because the agents' social network is 541 strongly connected in this scenario, they adopt the forecasts at a higher pace as the number of 542 adopters increases. This phase of the diffusion process (50 < t < 70) is known as the *take-off* 543 544 phase. As the number of potential adopters decreases, the rate of adoption decreases until an adoption ceiling or equilibrium is reached. 545

546 One of the key elements in the diffusion of innovations is the social system within which diffusion occurs (Rogers, 2003). Figure 6 demonstrates how the diffusion pattern is influenced 547 by the structure of a social network. The diffusion curve is almost linear when there is no 548 interaction between agents (i.e.  $SI_{in} = 0$ ,  $SI_{out} = 0$ ), which can be attributed to the linear form 549 of the learning function selected for the reinforcement-learning mechanism. When agents interact 550 with each other, particularly in the full-interaction scenario, both individual and social learning 551 552 mechanisms contribute to the forecast adoption and diffusion process, and therefore the forecast diffusion curve becomes non-linear. 553

554 Figure 6 also shows that, in the absence of social interaction, the number of adopters is higher at first than in either of the other two scenarios; with full interaction, on the other hand, 555 agents begin adopting the forecast later than in either of the other two scenarios. In addition, the 556 final adoption rate is highest when there is full interaction between agents, whereas almost 30 557 percent of the population decides not to follow the forecasts at the end of the simulation in the 558 no-interaction scenario. These patterns can be explained by considering the spatial and temporal 559 dynamics of diffusion. First, because risk aversion and initial wealth are randomly assigned, 560 agents' crop-allocation decisions vary; hence, the *ex post* values of forecasts vary across agents 561 (see Movie S1). Similarly, the learning rate is also randomly assigned. Therefore, the same 562 forecast can lead to varying adoption tendencies. When agents interact with their neighbors, their 563 forecast-adoption tendencies are essentially a weighted average of their own tendencies and 564 those of their neighbors. As such, the forecast-adoption tendencies are balanced or smoothed by 565

neighbors' tendencies, particularly when both inter- and intra-county interactions are present. When there is no interaction, though, an agent's belief about adoption is influenced only by his or her own experience (i.e. individual learning). In this case, there is no continuity or specific spatial pattern in the way the forecast is adopted by agents (see Movie S1). When intra-county ties or full interactions exist, however, there is a strong spatial correlation in forecast adoption, and it spreads from early adopters to the entire population.

572

Figure 6. Diffusion curves under multiple interaction scenarios: full interaction (i.e.  $SI_{in} = 1$ ,  $SI_{out} = 1$ ), intra-county interaction only (i.e.  $SI_{in} = 1$ ,  $SI_{out} = 0$ ), and no interaction (i.e.  $SI_{in} = 0$ ,  $SI_{out} = 0$ ).

Because forecasts are more accurate on average than climatological information (the 577 Brier skill score varies between 0.19 and 0.45 across the 25 counties), forecast adoption is 578 579 expected to produce an economic gain. If forecasts were adopted by all the agents from the beginning  $(Z_{i,1} = 1)$ , the total economic gain will on average be 29 percent (± 7 percent) higher 580 than in the case of relying only on climatological information the entire time, which we call the 581 baseline scenario hereafter. These results indicate that forecast adoption is a dynamic process 582 and the timing and rate of adoption depends not only on agents' characteristics but also on the 583 structure of the social network. As a result, the average increase in total economic gain with 584 respect to the baseline scenario is 9 percent ( $\pm$  7 percent) in the full interaction scenario. 585

Figure 7 demonstrates how forecast adoption and diffusion are influenced by the learning 586 rate, initial wealth, and risk aversion in the full interaction scenario. Figure 7a shows that 587 588 adoption starts earlier and reaches its maximum level more quickly as the learning rate increases. When the learning rate is low ( $\mu_{\tau} = 1.5$ ), adoption does not occur until t = 68, and at the end of 589 the simulation the adoption rate is only around 40 percent. This is because it takes a long time 590 for an agent to form a *positive opinion* (i.e. an opinion that leads to choosing adoption) about 591 592 forecasts when the learning rate is low. When  $\mu_{\tau} = 1.5$  and there is no interaction between agents, adoption starts earlier (around t = 45) but remains under 40 percent at the end of the 593

simulation (see Figure S7). As the learning rate increases, the diffusion curves in various social 594 595 interaction scenarios begin to resemble one another (see Figure S7), implying that the social structure becomes less important for the diffusion of forecasts when agents learn quickly from 596 the consequences of their own actions. The results shown in Figure 7b and Figure 7c show that 597 diffusion curves shift leftward as initial wealth increases or risk aversion decreases. In other 598 words, higher values of  $\omega$  or lower values of r result in earlier adoption and quicker diffusion, as 599 in Figure 5b and Figure 5c, because increasing  $\omega$  or lowering r increases an agent's willingness 600 to adopt forecasts. 601

602

Figure 7. Diffusion curves in various scenarios of (a) the learning rate, (b) initial wealth, and (c) risk aversion.  $\omega \sim N(0.5, 0.05)$  and  $r \sim N(7.5, 1.5)$  in (a),  $\tau \sim N(3, 1)$  and  $r \sim N(7.5, 1.5)$  in (b), and  $\omega \sim N(0.5, 0.05)$  and  $\tau \sim N(3, 1)$  in (c).

#### 607 **5 Discussion**

In this section, we use the ABM of forecast adoption to investigate how behavioral, contextual, and technological factors influence adoption behavior and the diffusion of forecasts.

#### 610 5.1 Impact of Change Agents and Strategic Targeting

It seems possible to facilitate forecast adoption by educating agents about the potential 611 612 value of forecasts, for example through local extension services, crop advisors, or boundary organizations (Buizer et al., 2016; Mase & Prokopy, 2014; Templeton et al., 2018). The impact 613 of such educational programs can be modeled as an increase in agents' initial propensity towards 614 forecast adoption (i.e.  $h_{i,1}$ ). Because it may not be feasible to target the entire population with an 615 educational program, here we consider an extension program like the Training and Visit 616 Extension System (Feder & Slade, 1986; Munshi, 2004), where extension agents target only a 617 portion of farmers in each designated region (Feder & Slade, 1984). Those farmers are referred 618 619 to as *change agents* or *contact farmers*. To illustrate this phenomenon, we consider the entire case-study area as one extension region and treat all agents in county 13, located in the middle of 620 the case-study area, as change agents. 621

For change agents (i = 301, 302, ..., 325), we set  $h_{i,1} = h_i^*$  and assume that they adopt 622 forecasts from the beginning. Figure 8a shows that, with change agents in the system, the 623 diffusion curve is shifted to the left and the diffusion process takes off earlier. The take-off phase 624 develops slowly at first (30 < t < 50), though, as forecast adoption first spreads among agents 625 located in change agents' neighborhoods. A stronger tendency towards adoption among these 626 agents together with an increase in the adoption tendency among other agents based on 627 individual learning results in a rapid increase in the adoption rate during the period 50 < t < 60. 628 After t = 60, there is a small percentage of non-adopter agents left. As a result, the adoption rate 629 decreases, and an adoption ceiling is reached (see Movie S2). 630

631 Figure 8b demonstrates the impact of the learning rate on forecast diffusion in the presence of change agents. When the learning rate is low (i.e.  $\mu_{\tau} = 1.5$ ), change agents have a 632 significant impact on the diffusion process: the adoption rate reaches the maximum of 76 percent 633 when change agents are present compared with the maximum of 48 percent without change 634 agents. When the learning rate is high (i.e.  $\mu_{\tau} = 4$ ), change agents have a smaller impact on the 635 diffusion process: the diffusion curves with and without change agents are almost identical. This 636 pattern confirms our earlier finding that the structure of the social network becomes less 637 important in the diffusion process as the learning rate increases. 638

639

Figure 8. Impact of change agents on the diffusion process when all agents in county 13 are targeted. (a) Full interaction scenario with  $\tau \sim N(3,1)$  and (b) full interaction scenario with  $\tau \sim N(1.5,0.5)$  and  $\tau \sim N(4,1)$ . Note that  $\omega \sim N(0.5,0.05)$  and  $r \sim N(7.5,1.5)$ 

643

Our model can also be used to test the effectiveness of extension programs and design 644 more efficient targeting strategies. For instance, selecting change agents is a key factor in the 645 success of such extension methods as training & visit (Feder & Slade, 1984). While opinion 646 *leaders* in farming communities are often selected as change agents, when information flows less 647 smoothly in a social system it may be necessary to rely on less subjective measures to select 648 change agents. To demonstrate this effect, we select agents whose initial wealth is above the 90<sup>th</sup> 649 percentile of the wealth distribution as change agents. The rationale for this selection is that, as 650 shown in Figure 5c and Figure 7c, agents with greater initial wealth exhibit a higher forecast 651 adoption tendency early in the simulation. Figure 9a shows that targeting wealthier agents 652 influences the diffusion process only slightly because, unlike in the previous example where all 653 agents in one county were targeted, wealthy agents, scattered throughout the study area, are 654 equally influenced by their neighbors, who have weaker adoption tendencies (recall that in the 655 full interaction scenario,  $\alpha_{ii} = \alpha_{ij}$  for  $j \in \mathcal{N}_i$ , i.e. self-reliance equals the weights given to each 656 neighbor). As change agents become more self-reliant (i.e. as  $\alpha_{ii}$  increases), however, they 657 continue influencing their neighbors while being influenced by their neighbors to a lesser extent. 658

As a result, they facilitate the diffusion process: the diffusion curve shifts further to the left, implying a quicker take-off and a higher adoption rate in the short and medium runs (see Figure 9b and Movie S3).

662

Figure 9. (a) Impact of wealthy agents as change agents on the diffusion process. (b) Impact of change agents' self-reliance (i.e.,  $\alpha_{ii}$ ) on the diffusion process where wealthy agents are targeted as change agents.  $\tau \sim N(3,1)$ ,  $\omega \sim N(0.5,0.05)$  and  $r \sim N(7.5,1.5)$ .

# 667 **5.2 Impact of Asymmetrical Learning**

In the reinforcement-learning algorithm used in this study (Equation 5), we use a single 668 learning rate to represent learning from both rewarding and punishing outcomes. Yet behavioral 669 studies suggest that rewarding and punishing outcomes may not have symmetric impacts on 670 decision-making (Cazé & Van Der Meer, 2013; Frank et al., 2004, 2007; Gershman, 2015). In 671 particular, most studies have found that a negative learning rate (corresponding to punishing 672 outcomes) is generally higher than a positive learning rate (corresponding to rewarding 673 outcomes) (e.g. Rasmussen and Newland (2008), Niv et al. (2012), and Gershman (2015)), 674 although some studies have found evidence of optimistic reinforcement learning, which is known 675 as optimism bias (Lefebvre et al., 2017). Here, we modify the reinforcement-learning algorithm 676 (Equation 5) to exhibit such asymmetrical updating, also known as asymmetry in the law of effect 677 678 (Rasmussen & Newland, 2008). To do so, we use a parameter called the *asymmetric learning* 

679 *coefficient* (denoted by  $\gamma$ ) to amplify the impact of punishing outcomes:  $L(S, \tau) = S \cdot \gamma \cdot \tau$ , 680 where  $\gamma = 1$  if  $S \ge 0$  and  $\gamma > 1$  if S < 0.

Figure 10 shows how asymmetrical learning influences the diffusion process. In the case 681 of symmetric learning (i.e.  $\gamma = 1$ ), the rate of learning is the same for rewarding and punishing 682 outcomes. Therefore, the diffusion curve is the same as the one shown in Figure 6. However, as 683  $\gamma$  increases, adoption starts later and the diffusion occurs at a slower pace (or, in the case of 684  $\gamma = 3$ , it never occurs) (see Movie S4). As  $\gamma$  increases, punishing outcomes (e.g. when a drought 685 event is proceeded by a low  $p_d$ ), which exert negative reinforcement strength, will have a greater 686 impact on a DM's learning. That is, when S < 0, the forecast-adoption tendency decreases to a 687 greater extent for a DM with higher  $\gamma$ . As can be seen, when  $\gamma > 2$ , the adoption tendency 688 almost never exceeds the adoption threshold, which implies that forecasts are never adopted over 689 the simulation period. 690

691

Figure 10. Impact of asymmetrical learning on forecast adoption. (a) Diffusion curves for the system in several asymmetrical learning scenarios, where  $\omega \sim N(0.5, 0.05)$ ,  $r \sim N(7.5, 1.5)$ , and  $\tau \sim N(3,1)$ . (b) Time series of forecasts and the evolution of the forecast-adoption tendency for a representative agent.

#### 697 **5.3 Impact of Forecast Accuracy**

Figure 11 shows the impact of forecast accuracy on forecast diffusion. The diffusion curves are averaged across 15 realizations of a forecast time series (also see Figure S8 for the ensemble envelope). When  $\kappa < 0.65$ , instances with  $V^{exp} < 0$  occur rather frequently; as a result, a DM's tendency to adopt forecasts never exceeds the threshold (see Figure S9). This implies that forecasts below 65 percent accuracy may never be adopted. This finding is consistent with those reported in other studies that have found that accuracy of at least 65 percent is required for seasonal forecasts to achieve long-term trust and adoption (see Ash et al. (2007) for a review). As forecast accuracy ( $\kappa$ ) increases, though, the take-off phase of the diffusion occurs earlier, and the adoption rate reaches its ceiling more quickly.

707

Figure 11. Impact of drought-forecast accuracy on the diffusion process.  $\omega \sim N(0.5, 0.05)$ ,  $r \sim N(7.5, 1.5)$ , and  $\tau \sim N(3, 1)$ .

710

#### 711 6 Conclusion

We develop an agent-based model to study the dynamic aspects of forecast adoption and 712 713 demonstrate the impacts of farmers' characteristics and social network structure on forecast diffusion. To address forecast users' imperfect knowledge of forecasts, we model their forecast 714 adoption as a stochastic choice and show that users' forecast-adoption tendencies evolve over 715 time as a function of the consequences of their past decisions as well as the decisions of their 716 717 neighbors. In addition, we show the influence of multiple factors on learning processes, including risk attitude, wealth, and the learning rate. We find that users with lower risk aversion, 718 719 greater wealth, and higher learning rates exhibit a stronger tendency to use forecasts and therefore adopt forecasts more quickly than others. 720

721 The ABM provides a flexible tool that helps us better understand how a range of economic, behavioral, social, and forecast-related parameters influence forecast adoption and 722 diffusion. Results derived from numerical experiments yield important insights into the effects of 723 social interactions and social networks on the dynamics of forecast diffusion. In particular, when 724 social interactions between agents take place, forecast diffusion follows a typical S-shaped curve, 725 as suggested in the diffusion-of-innovation literature. In contrast, when social learning is 726 ignored, the adoption pattern is (mainly) linear (Figure 6). Our results also show that, in a no-727 interaction scenario, the diffusion process starts earlier, reflecting the heterogeneities associated 728 with farmers' characteristics but reaches a lower adoption ceiling compared with what occurs in 729 a full interaction scenario. Moreover, our results show that asymmetrical learning reflecting the 730

asymmetry of reinforcement and punishment in human choice could significantly slow the diffusion process and lower the equilibrium adoption rate. On the other hand, we find that social structure has a limited impact on the diffusion process when the learning rate is high. Finally, we find that forecasts must be at least 65 percent accurate to be widely adopted and diffused in the system, which is consistent with findings reported by other studies in the literature.

Despite several constraining assumptions made in developing the ABM (e.g. discrete 736 drought states), this model can provide valuable insights that enrich our understanding of the 737 parameters that influence the adoption of drought forecasts, which can in turn be used to 738 positively affect the adoption and diffusion of high-quality forecasts. In addition, once the model 739 is tested and verified using fieldwork studies, it can be used to test the effectiveness of various 740 intervention and targeting strategies and, ultimately, to develop more effective strategies and 741 policies for overcoming impediments to forecast adoption. Several complementary methods 742 743 could provide the necessary information for model validation: descriptive field studies, highly structured interviews, and laboratory or decision experiments. In a controlled laboratory 744 experiment of the type that is traditionally employed in experimental economics (Kagel & Roth, 745 2015), researchers could observe how decision-makers respond to forecasts in stylized but 746 reasonably realistic experiments (Millner, 2009; Sonka et al., 1988). Finally, given the 747 demonstrated importance of social network structure for the diffusion process, field-based 748 studies could also be used to represent a social network and its properties more realistically by 749 extracting and mapping social and information networks and empirically analyzing the impacts 750 of social networks and various social processes on the diffusion of forecasts. 751

752

### 753 Appendix A: Crop-Allocation Decision-Making

754 According to Equation 4, the optimal crop-allocation decision  $(x^*)$  depends on several factors, including the yield distribution (y), the cost function (c), initial wealth  $(\omega)$ , the 755 coefficient of risk aversion (r), and beliefs about drought  $(p_{\theta})$ . We make the following 756 assumptions throughout:  $y^{A}(0) = 0.06$ ,  $y^{A}(1) = 0.03$ ,  $y^{B}(0) = 0.08$ ,  $y^{B}(1) = 0.01$ , c(1) = 0.01757 0.04, and c(0) = 0.05. Figure A1 shows how the optimal decision changes with r,  $p_{\theta}$ , and  $\omega$ . 758 For a risk-neutral DM (i.e., r = 0), the optimal decision is to plant only crop B (i.e.  $x_0^* = 0$ ) if 759  $p_1 < 0.5$ . As risk aversion increases, for any given  $p_1$  or  $\omega$ , a greater fraction of the land is 760 allocated to crop A because crop A yields exhibit much less weather-related variation, helping 761 risk-averse DMs minimize their risk exposure. Holding r constant, the fraction of land allocated 762 to crop A increases as a DM's belief about a drought occurrence  $(p_1)$  increases. This is because 763 crop A has a higher yield than crop B in drought conditions. Finally, more land is allocated to 764 crop B as  $\omega$  increases, as wealthier farmers' treatment of uncertainty more closely resembles that 765 of a risk-neutral DM. 766

Figure A1. Optimal crop-allocation decisions: (a) sensitivity analysis for  $p_{\theta}$  when  $\omega = 0.5$ , (b) sensitivity analysis for  $\omega$  when  $p_{\theta} = 0.3$ .

#### 771 Appendix B: Probabilistic Drought Forecast Generation

767

To compute the *ex post* value of forecasts, it is necessary to specify the time series of forecasts and drought realizations. One way to generate these time series is by using a joint distribution of forecasts and droughts, i.e.  $f(\varphi, p_d)$ . We use an approach similar to ensemble forecasting to generate probabilistic drought forecasts based on a specified accuracy.

Assume that the time series of dichotomous drought events ( $\varphi_t$ ) is known ( $\varphi_t = 1$ 776 indicates drought,  $\varphi_t = 0$  indicates no drought). The system generates N deterministic forecasts 777 of the dichotomous event at each time step t at accuracy  $\kappa$ . Each deterministic forecast  $(\eta_{i_t})$  is 778 referred to as an ensemble member, where  $i \in [1, N]$ . We assume that  $\eta_{i_t}$  is a Bernoulli process, 779 defined as follows: 780

where  $Be(1,\kappa)$  indicates a binomial distribution with one trial and probability  $\kappa$  of success. 782 783 Once N ensemble members are produced,  $p_d$  is calculated as:

784 
$$p_{d_t} = \frac{\sum_{i=1}^{N} I_{\{\eta_{i_t}=1\}}}{N}$$
 (B2)

785

where  $\begin{cases} I_{\{\eta_{i_t}=1\}} = 1 & \eta_{i_t} = 1 \\ I_{\{\eta_{i_t}=1\}} = 0 & if & \eta_{i_t} = 0 \end{cases}$ . The above definition has an undesirable property in that  $p_{d_t}$ 

could become zero or one, especially if N is small. Therefore, several post-processing methods 786 have been suggested to account for finite ensemble size (Katz & Ehrendorfer, 2006; Roulston & 787 Smith, 2002). We use: 788

789 
$$p_{d_t} = \frac{\left(\sum_{i=1}^{N} I_{\{\eta_{i_t}=1\}}\right) + 0.5}{N+1}$$
(B3)

In generating synthetic probabilistic drought forecasts, we also consider the possibility of 790 low-probability events with no or limited predictability, such as the 2012 flash drought in the 791 792 U.S. Midwest (Hoerling et al., 2014), by drawing a random number from a Bernoulli distribution Be(1,0.01) and flipping  $\kappa$  (i.e. using  $1 - \kappa$  instead of  $\kappa$ ) in Equation B1 if that random number 793 equals 1. 794

A list of mathematical notations used in the study is presented in Table C1.

#### **Appendix C: List of Symbols** 795

796 797

#### Table C1. Glossary of Notations

Symbol	Definition
<i>c</i> (θ)	non-land cost of crop production (e.g. fertilizers, see, labor) as a function of state of the weather, expressed in unit $u$
$E[\bullet]$	expectation operator
h	Forecast-adoption tendency; $h \in [0,1]$
$h^*$	adoption threshold or cut-off, $h^* = 0.65$
$L(\bullet)$	learning function in the reinforcement-learning framework
${\mathcal M}$	set of agents
т	total number of agents; $m = 625$
$\mathcal{N}_{i}$	set of neighbors of agent <i>i</i>
n <sub>i</sub>	total number of neighbors of agent <i>i</i>
$p(\theta)$	user's belief about the occurrence of state $\theta$ of the random weather event

$p_1$	user's belief about the occurrence of drought: $p_1 = p(\theta = 1)$
$p_d$	probabilistic drought forecast: $p_d \in [0,1]$
r	coefficient of risk aversion, $r \ge 0$
S	reinforcement strength, expressed in unit <i>u</i>
SI.	binary parameter indicating whether agents have social connections with
SIin	neighbors <i>in</i> their counties; a connection exists if $SI_{in} = 1$ .
SI .	binary parameter indicating whether agents have social connections with
Jiout	neighbors <i>outside</i> of their counties; a connection exists if $SI_{out} = 1$ .
t	time index
Т	total number of time steps; $T = 625$
$U(\bullet)$	utility function
и	baseline unit used for $y(\theta), \pi, \omega_0, V^{exp}, W$
$V^{exp}$	ex post value of forecast, expressed in unit u
WZ	Wealth, at the beginning of each time step, expressed in unit $u$ ; $W_1$ is initial
~ ~ ~	wealth.
x	decision variable: fraction of land allocated to crop $A, x \in [0,1]$
<i>x</i> *	optimal crop-allocation decision
<i>X</i> *, <i>C</i>	optimal crop-allocation decision based on $p_{\theta}$ (or climatology)
<i>x</i> *, <i>f</i>	optimal crop-allocation decision based on $p_d$ (forecast)
$y(\theta)$	crop yield as a function of the weather, expressed in unit <i>u</i>
$y_0$	crop yield in normal conditions ( $\theta = 0$ )
<i>y</i> <sub>1</sub>	crop yield in drought conditions ( $\theta = 1$ )
Ζ	forecast adoption decision, $z \in \{0,1\}$
α	extent/strength of social interaction between agents $i$ and $j$ ;
α <sub>l</sub> j	weight assigned by agent <i>i</i> to agent <i>j</i> 's belief
γ	coefficient of asymmetric learning
$\Delta = [\alpha_{ij}]$	<i>m</i> -by- <i>m</i> matrix of social interaction
η	deterministic drought forecast: $\eta \in \{0,1\}$
A	a set of possible states of the random weather event; of the binary drought event:
U	$\Theta = \{0,1\}$
A	random variable representing the uncertain weather event, $\theta \in \Theta$ ; $\theta = 0$ : no
U	drought, $\theta = 1$ : drought
К	forecast accuracy
$\pi(\bullet)$	normalized payoff function, expressed in unit <i>u</i>
τ	the learning rate
$\phi$	a set of possible realized states of the event; for a binary drought event: $\phi = \{0,1\}$
φ	observation of the event, $\varphi \in \Phi$ ; $\varphi = 1$ : drought, $\varphi = 0$ : no drought

## 798 Acknowledgments, Samples, and Data

We acknowledge funding support from the NOAA Climate Program Office's Coping with Drought Initiative (grant number NA18OAR4310257). The data used in this study, including drought event time series, forecast time series, and agents' parameters, are provided in Data Set S1 and Data Set S2.
